

Scaling from Metawebs to Realised Webs: A Hierarchical Approach to Network Ecology

Tanya Strydom ¹; Alexander Dunhill ²; Jennifer A. Dunne ³; Timothée Poisot ^{4,5}; Andrew P. Beckerman ¹

Abstract: Ecological networks provide a powerful framework for representing and analysing biodiversity, yet their construction and interpretation embed diverse theoretical assumptions. This perspective examines how alternative food web representations encode distinct scales, processes, and conceptual boundaries. We develop a hierarchical framework linking five core processes - evolutionary compatibility, co-occurrence, abundance, diet choice, and non-trophic interactions, to the construction and inference of networks. Additionally we distinguish between the different ways in which we construct networks and demonstrate how each constrains the type and scope of ecological inference. By explicitly connecting network representation to underlying theory and data, we clarify how structural assumptions influence interpretations of biodiversity patterns, community stability, and responses to multiple stressors. We argue that progress in biodiversity and ecosystem science depends on a rigorous alignment between the conceptual foundations of network models, the processes they capture, and the ecological questions they seek to address.

Keywords: food web, network construction, biodiversity, scale and process, interaction modelling

At the heart of modern biodiversity science are a set of concepts and theories about species richness, stability, and function (Loreau & de Mazancourt, 2013). These relate to the abundance, distribution, functions, and services that biodiversity provides. Network representations of interactions among organisms are increasingly argued to be an asset to understanding and predicting the impacts of multiple, simultaneous stress on these core components of biodiversity (Simmons et al., 2021). Documenting interactions between and among taxa is thus one of the fundamental building blocks of community ecology and provides a powerful abstraction and platform for mathematical and statistical modelling of biodiversity to make predictions, and to mitigate and manage threats (Windsor et al., 2023).

However, there is a growing discourse around limitations to the interpretation and applied use of networks (Blüthgen, 2010; Dormann, 2023). Against this, it is important to evaluate the value and the limitations of the various network conceptualisations of biodiversity (Blüthgen & Staab, 2024). In this perspective we aim to provide an overview of different **food web** representations, particularly how each representation embeds assumptions about the processes that determine interactions (Section 2) about the levels of organization at which this occurs (*i.e.* the biological, ecological, spatial/temporal scales) and the way in which we construct the resulting networks (Section 3). The differences among this tri-partite set of assumptions ultimately influence the nature and scope of inference that can be made from a given network (Proulx et al., 2005).

Fundamentally, we are talking about an intersection of the type of data used to construct a network and the underlying theory as to what drives the resolution and occurrence of interactions among species in those data. We still lack a clear explanation of the different assumptions and scale dependent processes that underpin network construction alongside extensive discussions about the challenges relating to data collection and observation (*e.g.*, Blüthgen & Staab, 2024; Brimacombe et al., 2023, 2024; Moulatlet et al., 2024; Polis, 1991; Pringle & Hutchinson, 2020; Saberski et al., 2024). Such an understanding should deliver an acceleration in capacity to more effectively predict the impact of multiple stressors on biodiverse communities.

In their recent work, Gauzens et al. (2025) showcased a 2+2 decomposition of networks around aggregated versus species level resolution of nodes and around potential and realised links among the nodes. Their review delivers valuable insight into the methodologies used to collect and manage data among the node and link differentiation. It also delivers an overview of the scale and types of questions that are associated with each category of differentiation.

Here we provide a complementary perspective focused on concepts, models, and theory, in contrast to the data driven breakdown in Gauzens et al. (2025) (*e.g.* their Tables 1 and 2). Our approach delivers a hierarchical

perspective on network construction based on a gradient from feasibility, capturing the concept of metawebs and Gauzen et al’s ‘potential’ webs, through to realised webs as in Gauzens’ et al. In contrast to their 2 + 2 decomposition (their Fig 1), our perspective showcases nested ecological scales and processes that derive from shifts in the assumptions and theories embedded along this gradient. This includes classic ecological ‘aggregations’ such as functional/phylogenetic groups through to species, populations and individuals, unique perspective on how space and time intersect with node and link resolution, refined insight into which networks are derived by induction vs. deduction and a revealing of a core transition between assumptions about how links are derived based on evolutionary vs. ecological theories.

In the following sections we provide a scene-setting review of nodes and edges (links) in networks before aligning various processes that determine interactions with the different network representations. Ultimately, we provide a unique perspective on the nested hierarchy of processes that govern transitions from meta-webs to realised webs. We finish with a refined and nuanced alignment of models/representations and key questions in biodiversity science in the anthropocene.

1 Setting the Scene: The Not So Basics of Nodes and Edges

Networks in ecology have multiple uses, representing an ‘object’ from which inferences can be made. For example, a network is needed to make inferences about the structure of communities. The structure of networks - their topology - have a long history reflecting core theory about energy flow (Lindeman, 1942; Odum, 1968), function (Schneider et al., 2016) and stability (Brose et al., 2006; Danet et al., 2024; MacArthur, 1955). Networks are thus required as the response variable in evaluating ecological theory and statistical models of ‘generative processes’ giving rise to such structure. Such structure is now commonly used to compare communities along environmental gradients or time (Hao et al., 2025; Pecuchet et al., 2020). Networks and their topology are also used as a platform for evaluating ‘downstream’ responses to stressors such as evaluating patterns of secondary extinction (Keyes et al., 2024; Staniczenko et al., 2010). Finally, they are commonly used as a platform for implementing mathematical models of community dynamics (*e.g.*, Delmas et al., 2017); delivering inference about stability, function, invasive species, climate change, contaminants, and secondary extinction (*e.g.*, Curtsdotter et al., 2019), to name a few applications. Against this backdrop of multiple research agendas, the definition of ‘edges’ and ‘nodes’, and the levels of organisation at which they are defined, take many forms (Moulatlet et al., 2024; Poisot, Stouffer, et al., 2016), each of which encode a series of assumptions within a network. Here we introduce a perspective on these baseline assumptions.

1.1 How do we define a node?

While the convention is that nodes represent species, in practice nodes also represent other taxonomic units (e.g., sub-species, genera, families) as well as non-taxonomic units such as a trophic species (e.g., Yodanis (1982); Williams & Martinez (2000)), a feeding guild (e.g., García-Callejas et al., 2023), or a subset of a species defined by life stages (e.g., Clegg et al., 2018). Such granularity and variation is often defined as aggregation. Such aggregation can limit the ability to make species (taxonomic) specific inferences (e.g., does species *a* eat species *b*?). It can also affect the estimates of degree distributions and more specifically generality and vulnerability in networks (in/out degree). These metrics are central to inference about the structure and complexity of networks (Beckerman et al., 2006; Clegg et al., 2018). Finally, aggregation makes it challenging to use networks in ‘downstream analyses’ of, for example, extinction or invasions as the identity of species and the consequences of their losses can be hidden. Despite these issues, there are justifications for representing nodes as aggregated units. Most prominent relates to when the distribution of the links between aggregated nodes may be more meaningful in terms of understanding or making generalisations about the system e.g., tracking species extinctions across feeding guilds (Dunhill et al., 2024).

1.2 What is captured by an edge?

In order to break down the definitions of an edge, it is important to introduce the concept of *potential* versus *realised* links: potential links reflect feasibility while realised links are connected to flux of some currency (typically energy; see below for more detail). Links within food webs are thus a representation of either potential links between species Pringle (2020) or fluxes within a system e.g., energy transfer or material flow as the result of the feeding links between species (Lindeman, 1942; Proulx et al., 2005). Edges can thus correspond to different ‘currencies’ (Gauzens et al., 2025). There are also a myriad of ways in which the links themselves can be specified. Links between species can be treated as present or absent (i.e., binary), may be defined as probabilities (Banville et al., 2025; Poisot, Cirtwill, et al., 2016) or by continuous functions which further quantify the strength of an interaction (Berlow et al., 2004). How links are specified thus requires intersecting both the currency being modelled and their specification. For example, feasibility is unlikely to accommodate flux, but does align with binary or probability representations. Taking a food web that consists of links representing feasible interactions among a collection of species will be meaningless if one is interested in understanding the flow of energy through the network as the links are not environmentally/energetically constrained.

1.3 Network representations

Against these definitions of nodes and edges, networks fall into two major ‘types’: metawebs, traditionally defined as all the *potential* interactions for a specific species pool (Dunne, 2006); and realised networks, which is the subset of interactions in a metaweb that are *realised* for a specific community at a given time and place. The fundamental differences between these two network representations are the spatial and temporal scale at which they are constructed, and the associated processes that are assumed to drive patterns at these scales. A metaweb is, at its core, a list of *feasible* interactions between pairs of species. The feasibility for a given pair is derived from the complementarity of their traits, typically aligned with feeding. Feasibility can be further refined by *co-occurrence* leading to the transition from a *global* to *regional metaweb*. Metawebs thus provide a means to identify evolutionary plausible links, regionally plausible interactions, the set of ecologically impossible, *i.e.*, forbidden, links (Jordano, 2016b), and ultimately a definition of the plausible *complete* diet of a species (Strydom et al., 2023).

In contrast, realised networks are typically more localised in space and time, and the links between species are contingent on the co-occurrence of species, the role of the environment, and mechanisms of diet choice. Fundamentally this means that the presence/absence of a link is the result of the ‘behaviour’ of the species and even when the realised network is presented as a binary matrix, the edges imply a function is available to define the strength of an interaction. A realised network is therefore not simply the downscaling of a metaweb to a smaller scale (*e.g.*, moving from the country to the 1x1 km² scale based on fine-scale species co-occurrence). Instead, realised webs capture processes that determine the realisation of an interaction and flows of energy in a community. Specifically, in realised webs, the definition of an edge shifts from being determined by feasibility to that of choices and consequences that centre around energy. If one were to take the same community of species and construct both a metaweb and realised network the two networks might have the same species but would be structurally different, owing to the differences in the ‘rules’ constraining the presence of links. This distinction between metawebs and realised webs leads to a further insight. Links that are absent in a metaweb can conceptually (although not always practically) be treated as being truly absent. However, links that are absent in a realised network cannot be considered as truly absent but rather as absent due to the broader environmental/community context.

2 From Nodes and Edges to Process and Constraints

In the previous section we discussed how the definition of nodes and edges, representing different scales and processes, lead to the concept of a metaweb and a realised web. The fundamental take-homes are that nodes

vary in their resolution, edges vary in what kind of process they represent and the intersection of these, defined by meta- vs. realised webs, underpins distinct lines of inquiry and constraints on the type of inference we can make with networks. Here we reveal five core constraints across evolutionary and ecological scales that further delineate the transition from meta- to realised webs, exposing processes that determine the nature of links among nodes: evolutionary compatibility, co-occurrence, abundance, diet choice, and non-trophic interactions Figure 1.

[Figure 1 about here.]

2.1 Processes that determine the feasibility of an interaction

Evolutionary compatibility and co-occurrence are the two principle processes that ‘act’ at the species pair of interest and define feasibility. The scale of inference and set of processes embodied in these two constraints typically combine to define a ‘list’ of interactions that are viable/feasible and defined strictly as present/absent. Reflecting on the previous section, nodes are typically species and rules defining edges are defined by trait complementarity (phylogenetic) and/or co-occurrence. Here we provide more insight into each process.

Evolutionary compatibility

This constraint is defined by shared (co)evolutionary history between consumers and resources (Dalla Riva & Stouffer, 2016; Gómez et al., 2010; Rossberg et al., 2006; Segar et al., 2020) which is manifested as ‘trait complementarity’ between two species (Benadi et al., 2022). In this body of theory, the consumer has the ‘correct’ set of traits that allow it to acquire and consume the resource. Interactions that are not compatible are defined as forbidden links (Jordano, 2016b); *i.e.*, they are not physically possible and will *always* be absent within a network.

Networks do not properly arise from models based on this constraint. Instead, interacting species pairs are defined and these are represented as binary (possible vs forbidden) or probabilistic (Banville et al., 2025). For example, in the metaweb constructed by Strydom et al. (2022) probabilities are quantified as the confidence of a specific interaction being *possible* between two species. A network constructed on the basis of evolutionary compatibility is conceptually aligned with a ‘global metaweb’, and gives us information as to the global feasibility of links between species pairs despite the fact that they do not co-occur (see Figure 1).

(Co)occurrence

The co-occurrence of species in both time and space is a fundamental requirement for an interaction between two species to occur (at least in terms of feeding links). Although co-occurrence data alone is insufficient for building an accurate and ecologically meaningful representation of *feeding links* (Blanchet et al., 2020), it is

still a critical process that determines the possible realisation of a feeding. Knowledge on the co-occurrence of species allows us to spatially constrain a global metaweb to reflect regional metawebs (Dansereau, Barros, et al., 2024). In the context of Figure 1 this would be the metawebs for regions one and two.

We reinforce that these two constraints don't deliver a network *per se*, but a list of feasible species pairs. Although it is possible to build a network from the list of interactions generated by these constraints, it is important to be aware that the structure of this network is not constrained by any community context: just because species are able to interact does not mean that they will (Caron et al., 2024; Poisot et al., 2015).

2.2 Processes that realise networks

In contrast to the above, here we highlight three processes that influence the *realisation* of an interaction between species and thus form the conceptual basis for realised networks. As we show in Figure 1, a 'truly realised' network is the product of properties of the community (**abundance** and **non-trophic interactions**) and the individual (**diet choice**). This represents a conceptual shift from considering the feasibility for species pairwise interactions to considering the edge as a representation of energy flow. Such a transition requires information about how the community, the environment and the individual *constrains* network topology as defined by consumer choice (Quintero et al. (2024), Section 1.3)

Abundance

Abundance as a realising process emerges from a null model for energy acquisition: organisms feeding randomly will consume resources in proportion to their abundance (Stephens & Krebs, 1986). Here, abundance of different prey species influences the distribution of links in a network (Vázquez et al., 2009) by defining a preference linked to individuals among species meeting (Banville et al., 2025; Poisot et al., 2015). Abundance data (linked to a derived metaweb) delivers a foundation ruleset that can define the distribution and strength of links. Of note, however, is that such abundance constrained interactions are not necessarily contingent on there being any compatibility between species (E. Canard et al., 2012; Momal et al., 2020; Pomeranz et al., 2019).

Diet choice

It is well established that consumers make more active decisions than eating items in proportion to their abundance (Stephens & Krebs, 1986). Ultimately, consumer choice is underpinned by an energetic cost-benefit framework centered around profitability and defined by traits associated with acquisition and consumption of a resource (Smith et al., 2021; Wootton et al., 2023). Energetic constraints are invoked to construct networks in a myriad of ways (*e.g.*, Beckerman et al., 2006; Cherif et al., 2024; Pawar et al., 2012; Portalier et al., 2019).

In contrast to metaweb ‘construction’ from a list of pairwise interactions, these methods deliver a realised web directly and as an emergent property of node behaviour. We also here make a distinction, developed below, with models like the Niche Model (Williams & Martinez, 2000), where diet choice is implicit in its probabilistic network generating function, but it is working to replicate the *expected* structure of the network and this structure does not emerge from node-based rules. Note that we select diet choice as a term to capture rules linked to optimal foraging (Pyke, 1984) and metabolic theory (Brown et al., 2004); it is a sensible ‘umbrella concept’ for capturing the energetic constraint on of the distribution and strength of interactions.

Non-trophic interactions

We include non-trophic interactions (see Miele et al., 2019) here not as a determinant of links, but a modifier of them - they are the community context above and beyond co-occurrence and abundance. Non-trophic interactions include competition for space, predator interference, refuge provisioning, recruitment facilitation as well as non-trophic effects that increase or decrease mortality. These interactions (Ings et al., 2009) specifically modify either the realisation or strength of trophic interactions (Golubski & Abrams, 2011; Kamaru et al., 2024; Pilosof et al., 2017; Staniczenko et al., 2010) and represent direct (e.g., predator *a* outcompetes predator *b*) and indirect (e.g., mutualistic/facilitative interactions) mechanisms. They operate on the realisation of a network by altering the fine-scale distribution and abundance of species and relative contributions of direct and indirect effects to biomass, persistence, stability and the functioning of the communities (Buche et al., 2024; Kéfi et al., 2012, 2015; Miele et al., 2019).

3 Network construction

The above five processes are central to understanding the assumptions inherent in building different types of networks. Each of the processes, or combinations thereof, deliver a unique set of boundary conditions on what a network represents and can be used for. Here we build on the introduction of these five processes to further categorise the approaches to constructing networks. In doing so also introduce more detail on a variety of methodologies used to construct networks.

3.1 Why construct networks?

Networks are a representation of biodiversity. In a perfect world, we might know about all interactions. However, the empirical collection of interaction data is both costly and challenging to execute (Jordano, 2016a, 2016b; Poisot et al., 2021). In the absence of robust empirical data, we construct models that facilitate interpolation and gap-filling of existing empirical datasets (*e.g.*, Biton et al., 2024; Dallas et al., 2017; Poisot

et al., 2023; Stock et al., 2017), predict the feasibility of interaction among pairs of species, or directly predict network structure (see Strydom et al., 2021 for a broader discussion).

They are unique in delivering more than just estimates of species richness. As noted in the introduction, a network embodies the organising structure of biodiversity and allows numerous opportunities for ‘downstream’ analysis, including the comparison of structures, estimation of energy flux or extinction dynamics and ultimately form the structural inputs to dynamical systems models that facilitate ecological and conservation relevant inference about productivity-diversity-stability-function relationships (Danet et al., 2024) in space and time. But making such inferences requires careful attention to one or more of the processes discussed in Section 2.

3.2 Construction through induction

Constructing feasible or realised networks can be framed as an ‘inductive reasoning’ process where insight and generalisation arises from a set of observations and relationships. Inductive reasoning as a foundation for network construction is implemented at node and network levels. When applied at the node level, species-specific networks are created and judged by their association with expected feeding interactions. When applied at the network level, networks are judged by their structural properties.

3.2.1 Species specific networks: construction through node level induction

Constructing feasible networks and facilitating the interpolation or gap-filling of existing empirical datasets on sets of species interactions can be framed as an ‘inductive reasoning’ process where insight and generalisation arises from a set of observations and relationships about feeding. All methods in this inference space rest on a set of three assumptions: there are a set of ‘feeding rules’ that underpin interaction feasibility (Morales-Castilla et al., 2015); these rules are phylogenetically conserved (Bramon Mora et al., 2018; Dalla Riva & Stouffer, 2016); and they can be specified by matching the traits between consumer and resource.

Evolutionary compatibility and co-occurrence constraints, have been critical to the construction of ‘first draft’ networks for communities for which we have no interaction data (Strydom et al., 2022). They are also central to interpolation in data poor regions and predicting interactions for ‘unobservable’ communities *e.g.*, prehistoric networks (Dunhill et al., 2024; Fricke et al., 2022; Yeakel et al., 2014) or future, novel community assemblages (Van der Putten et al., 2010). Furthermore, they have the capacity to evaluate a role of interactions among species relative to their distribution by accounting for the role of the environment and the role of species interactions (Gravel et al., 2019; Higino et al., 2023; Pollock et al., 2014). There are substantial data requirements for these approaches including expert knowledge, species traits and phylogenetic

relationships and/or interaction data on related species or communities.

Feeding rules are defined in multiple ways. The determination of the feeding rules can be defined *a priori* based on expert knowledge opinions. Typically this is done on a ‘trait matching’ basis. An example are the paleo food web models of Shaw et al. (2024) and Roopnarine (2017) that specify a series of rules for a set of traits and interactions deemed feasible if all conditions are met. Alternatively the body size ratio between the consumer and resource is often used (*e.g.*, Gravel et al., 2013; Rohr et al., 2010), with the idea that consumers will only utilise a resource with a body size is less than or equal to their own. However, work from Van De Walle et al. (2023) seems to suggest that adding morphological traits in addition to body size ratio improves model performance.

Rules are also defined by correlating real world interaction data with suitable ecological proxies for which data is more widely available (*e.g.*, traits) using some sort of binary classifier (see Pichler et al. (2020) for an overview). These include generalised linear models (*e.g.*, Caron et al., 2022), random forest (*e.g.*, Llewelyn et al., 2023), trait-based k-NN (*e.g.*, Desjardins-Proulx et al., 2017), and Bayesian models (Cirtwill et al., 2019; *e.g.*, Eklöf et al., 2013).

Finally, graph embedding uses the structural features of a known network to infer the position of species in an unknown network through the decomposition of the interaction onto the embedding space. This decomposition relies on a combination of ecological proxies (*e.g.*, traits) in conjunction with known interactions to infer the latent values of species, which can then be mapped onto decomposition of a known network. See Strydom et al. (2023) for a detailed review of methods and Strydom et al. (2022) for a specific example.

3.2.2 Species agnostic networks: construction through structure induction

Networks in this category are generated using rules that create non-random networks that reflect some minimal empirical knowledge of ecological networks. These can be used in a variety of ways, for example comparing the structure of observed (realised?) networks to quantify relative deviations from the model structure. They are also used as a way to generate ‘realistic’ food web structures that are used for dynamical or other analyses. The determination of links between species is only implicitly linked to properties of the nodes. This means these networks are usually not species specific. Although these models are data input light, often requiring only species richness and an estimate of the number of expected links, they make clear assumptions regarding what the expectations are for network structure. These are some of the most commonly used network generation tools (*e.g.*, the Niche model; Williams & Martinez (2000)). There are two sub-categories of these species agnostic networks.

Stochastic network models use a probabilistic rule-set about diet choice and niche breadth to reflect fundamental ideas of foraging biology. These models that are based on the compartmentalisation and acquisition of energy for species at different trophic levels (Allesina & Pascual, 2009; Krause et al., 2003) and that network structure can be determined by distributing interactions along single dimension [the ‘niche axis’; Allesina et al. (2008)]. Typically these models parametrise some aspect of the network structure (although see Allesina & Pascual, 2009 for a parameter-free model). These models include the most commonly used network generator, the Niche model (Williams & Martinez, 2000), as well as the original Cascade model (Cohen et al., 1990) and the derived Nested hierarchy model (Cattin et al., 2004). These models often form the basis for dynamic models *e.g.*, the allometric trophic network (Brose et al., 2006; Schneider et al., 2016) and bioenergetic food web models (Delmas et al., 2017).

3.3 Construction through deduction

In contrast to the above approaches centered on feasibility, realised networks via methods reflecting abundance and diet choice typically rely on deductive reasoning and have a unique agenda to those above. In contrast to the inductive methods, inference about a realised network follows from a set of premises defining generative processes, often referred to as mechanisms. Typically, models that embed abundance and diet choice constraints reference theory that allows inference about the distribution and strength of interactions. Such models are ‘network topology generators’ and have a strong representation in research comparing network structures along environmental gradients and delivering inference about extinctions and energy flux. They also provide the structural backbone for dynamical systems modelling to address questions about stability-structure-productivity-function relationships, secondary extinction dynamics, species invasion and climate change. There are two broad groups of models in this deductive category.

3.3.1 Species-specific networks

These models capture the behaviour of the nodes by explicitly taking into account the properties of the different species in the community. Which means that there is a degree of variance in which links are predicted between species unlike the more ‘static’ predictions made by inductive models. However, these networks are ‘costly’ to construct in real world settings (requiring data about the entire community, as it is the behaviour of the system that determines the behaviour of the part) and also lack the larger diet niche context afforded by metawebs.

Neutral networks are built on the assumption that foraging decisions are tied *only* to the abundance of species within the community (E. F. Canard et al., 2014; Krishna et al., 2008). Here links are solely determined by the

relative abundance of the different species in the community. Although it is highly unlikely that abundance is the only determinant of interactions work by Pomeranz et al. (2019) showcases how these neutral processes can be used in conjunction with inductive models to construct more refined/localised networks.

There is a broader group of models that focus on determining interactions in terms of energetic constraints on diet breadth, often using the ratio of consumer-resource bodysize as a proxy for capturing the energetic constraints of feeding. Models such as those developed by Portalier et al. (2019) and Wootton et al. (2023) are similar to the mechanistic approaches discussed in Section 3.2, however instead of determining interactions based on mechanistic feasibility it is rather constrained by the energetic cost of predation. Note that although these models do not place any explicit constraints on the expected structure of the network, the links should still be considered as ‘realised’ owing to the energetic constraint placed on links. A different subset of diet models (*e.g.*, Beckerman et al., 2006; Petchey et al., 2008) use a diet choice approach, however similar to the stochastic network models they also embed assumptions on network structure. Thus these models predict both interactions and network structure simultaneously, although they would benefit in being refined by more explicitly accounting for trait-based (*i.e.*, feasibility) parameterisation (Curtsdotter et al., 2019).

4 Making Progress with Networks

The motivation to leverage network ecology in conservation ecology, environmental risk assessment and natural resource management stems from a shift away from species/population specific measures of the effects of stress and disturbance to community level metrics of these impacts. These metrics, such as resilience and more generally stability, ecosystem function and biodiversity *per se*, are natural properties of networks. This suggests that modern conservation, risk assessment and resource management requires robust network tools to support decision making.

This is also true in the disciplines of ecology and environmental science and their focus on abundance, distribution, functions and services that biodiversity provides (Loreau & de Mazancourt, 2013). Major questions remain, for example, about stability-diversity-productivity relationships, the impacts of extinctions and invasions and the impacts of multiple stressors operating at multiple ecological scales. A network approach to answering these types of questions specifically allows us to evaluate how environmental gradients and anthropogenic stress map through direct and indirect effects among species in a complex community and reveal fundamental patterns and understanding of processes in the natural world.

In order to effectively use networks to aid us in answering questions about conservation/risk assessment/management and core ecological theory, we need to be mindful that we are mapping the *correct* network representation

to the question of interest (Gauzens et al., 2025). Notably, there are certain questions that cannot be answered using specific network representations as the scale of the question of interest is fundamentally misaligned with either the process captured by a specific network representation Section 2.1, the underlying data that is used to construct it Section 3 or both of these factors.

Here we discuss and map the different network representations shown in Figure 1 to ‘appropriate’ research questions and agendas see also 1. We also highlight some of the key methodological challenges that currently limit our conceptualisation of a ‘network’ and thus impact their effective practical application in real world settings.

Table 1: Showcasing some of the broader avenues of inquiry, specifically how they map to the different network representations

Network Representation	Example Research Question
Global Metaweb	How will novel communities respond to <i>e.g.</i> , extinction, turnover, invasion and rewilding Diet-based conservation focusing not only on the target species but the species it might depend on for food resources Rewiring capacity/potential of species by looking at the <i>entire</i> diets of species Eco-Evolutionary dynamics and how they relate to the conservation and origination of feeding strategies
Regional Metawebs	Applied use potential of questions highlighted for global metawebs at the management scale <i>e.g.</i> , a protected area Refinement/extension of species distribution models by incorporating co-occurrence and species associations <i>e.g.</i> , predator and prey
Realised webs	The allocation of multiple stressors across networks Temperature threshold to community collapse Extinction and persistence after harvesting/invasion/extinction Stability-diversity-productivity-function

Network Representation	Example Research Question
	Explicitly tying ecosystem level processes and nutrient flows to networks
	Meta communities and the idea of meta-network-communities

4.1 Key Eco-Evo-Conservation Questions

4.1.1 Global Metawebs

The interactions in global metawebs are not constrained by the realisation of specific community assemblages (or species co-occurrence). These networks provide a platform for answering questions that assume interactions *could* occur between species (feasibility) or where the potential diet breadth of species is required. Examples of appropriate research questions at this scale includes those about *hypothetical* or *novel* communities and interactions under future climate change scenarios, or the potential ‘position’ of an invasive (or re-introduced) species within a network (Hui & Richardson, 2019). This scale is also appropriate for a particular class of questions related to the potential (eco-evolutionary) rewiring capacity of species, and how this may help inform on the opportunities for persistence of species within new community assemblages (Marjakangas et al., 2025). The implicit focus on feasibility in these examples highlights that global metawebs are linked to strong proxies for targets and mechanisms of evolutionary change. This offers a network scale for modelling ecological-evolutionary dynamics and the role that both evolutionary history, natural selection, and phenotypic plasticity shapes the diet breadth of species.

4.1.2 Regional Metawebs

Regional metawebs are conceptually a spatially constrained global metaweb. They make explicit the co-occurrence between species. Against this backdrop, they are conceptually aligned with similar questions to those posed above, with the added focus on a community facing, real-world, challenge. Additionally, regional metawebs can and have been used to refine and constrain species distribution model predictions, giving us more refined range maps (García-Callejas et al., 2023) or community composition under climate change scenarios, even at global scales (Hao et al., 2025).

However we must exercise a high degree of caution when comparing structures among regional metawebs, whether discrete collections or along environmental gradients. At this scale, where the network embeds the assumptions of feasibility, the link distribution is not meaningfully constrained by environmental factors (see

Section 1.2) and it is vital to disentangle structural change *per se* from the multiple processes that might determine species turnover (*e.g.*, β - diversity).

4.1.3 Realised networks

Realised networks are the most representative of what comes to mind when people think of networks, and more specifically how we can use them to help inform on larger biogeographic processes (Thuiller et al., 2024). This is partially because of the popularity and legacy of generative network models (like the Cascade and Niche model) which produce realised network representations, and represent the ideal ‘currency’ for which to understand the constraints placed on interactions/network structure by the broader community and environmental context. This change in currency and context affords us the opportunity to ask questions that revolve around major ecological theory - *e.g.*, community stability and resilience, biodiversity dynamics, ecosystem function, structure-function relationships - and around major conservation and climate change global challenges - *e.g.*, temperature change, extinction dynamics, invasion impacts and reintroductions/rewilding.

Realised networks embody an explicit focus on the link between network structure to ecosystem function. Because the structure of realised webs are isolated from turnover processes they allow us to think about the propagation of change (across both time and space) which allows us to ask questions about the persistence of communities and how they respond to perturbations or stressors (at both the level of the node as well as the modification of links). For example in Section 4.1.1 we discuss how global metawebs can inform as to the rewiring *capacity* of a species, a realised network however would be better suited to capture the rewiring of networks over time as a response to changes in the environment or community.

Although the recent boom in the availability of long-term observation data is allowing us to unpack decades of insights for stability-diversity-productivity relationships for more complex communities (Danet et al., 2024) or to evaluate the impacts and efficacy of re-introductions (Wooster et al., 2024), we need to be mindful that empirical interaction data is typically accumulated over time and so it compresses the transient nature of the interactions between species (Polis, 1991). Thus we need to apply a degree of caution when using empirical data to construct realised networks - although there is scope to think about developing methods that will allow us to modify metawebs in such a way that their structures become more aligned with realised webs (see the next section).

4.2 Key methodological challenges

As noted above, the three types of networks help highlight longstanding methodological challenges that affect our ability to increase both precision and accuracy of inference derived from the questions we highlight above.

Here we review some of these challenges and opportunities that are arising to mitigate them.

Understanding what empirical data represents: Ultimately, knowing what is right/precise/correct in an ecological network requires robust data. What does it mean when we ‘observe’ an interaction be that directly (predator actively feeding on prey) or indirectly via *e.g.*, gut or isotope analysis. A network constructed with empirical data will most likely still represent an ‘accumulation’ of feeding data making it conceptually more closely aligned with the idea of a metaweb.

The validation of network structure: Progress has been made in the development of tools and approaches of assessing how well a model recovers pairwise interactions (Poisot, 2023; Strydom et al., 2021), but we still lack a clear set of guidelines for benchmarking the ability of models to recover structure (Allesina et al., 2008). This makes it challenging to assess if models are capturing network structure accurately, especially if one wants to use empirical data as the ‘testing set’. Specifically, can we use a network constructed using long-term interaction observation data (*i.e.*, conceptually a metaweb) to assess the accuracy of a modelled (*I don’t know how I feel about this word*), realised network? Additionally one needs to think about *what* aspect of accurate/precise network construction is the most important - is it the structure or ability to correctly predict pairwise links? In the case of attempting to construct a metaweb it is important that one is accurately recovering both links that are truly present and absent, however in the case of realised webs it is perhaps not that clear. Is it sufficient to correctly recover structure *e.g.*, connectance or do the pairwise links also need to be correct?

Transitioning between metawebs and realised webs: Currently most approaches to modelling realised networks fail to explicitly account for any form of evolutionary constraint (although see Van De Walle et al. (2023) and Wootton et al. (2023)) and we need to develop either an ensemble modelling approach (Becker et al., 2022; Terry & Lewis, 2020) or tools that will allow for the downsampling of metawebs into realised networks, (*e.g.*, Roopnarine, 2006).

Importantly we need to think critically how the creation of either an ‘ensemble network’ or downsampled metaweb might change the underlying ‘currency’ of a network and thus the underlying definition of the edge *e.g.* the downsampling approach developed by Roopnarine (2006) structurally constrains the network to structurally look like a realised web, but the links do not represent prey choice *per se*.

Having a well developed framework as well as ‘fluidity’ to allow us to scale up between meta- and realised food webs lays the groundwork for us to actively begin the integration of food webs into the classical metacommunity-metacosystem space (Massol et al., 2011) as well as ecosystem level processes (Liu et al., 2025). The being said developments in the community-ecosystem space should be intentional about articulating

a firm distinction as to what defines a ‘network’ as a unit, as well as defining the logical (spatial and temporal) boundaries between networks (Fortin et al., 2021).

Making networks more tractable in applied spaces: There is a disconnect when it comes to effectively using networks in applied spaces. This is probably at least in part related to the challenges with delineating ‘boundaries’ between networks, and specifically how these relate to ‘management units’ and scales in addition to a limited interpretability of network metrics, specifically how this can be applied to conservation targets/indices (Dansereau, Braga, et al., 2024). In order to address these shortcomings we need to make an effort to more efficiently map the form (structure) of a network to its function in order to identify how this can effectively be integrated into policy to make it meaningful and actionable (O’Connor et al., 2025), all while remaining mindful to ensure that we identify the appropriate network representation.

5 Concluding remarks

Having a clear understanding of the interplay between network representations and the processes that they are capable of encoding is critical if we are to understand exactly which networks can be used to answer which questions. As we highlight in Section 4 the different network representations have different potential uses and it should be clear that there is no ‘best’ network representation but rather a network representation that is best suited to its intended purpose. In providing a formalisation regards to the assumptions and mechanisms that need to be explicitly taken into consideration when deciding to use (and construct) networks we hope to prevent the unintentional misuse or misinterpretation of networks as well as provide a starting point from which we can develop a better framework for the applied use of networks to answer questions that are not only pressing within the field but also within broader biodiversity science.

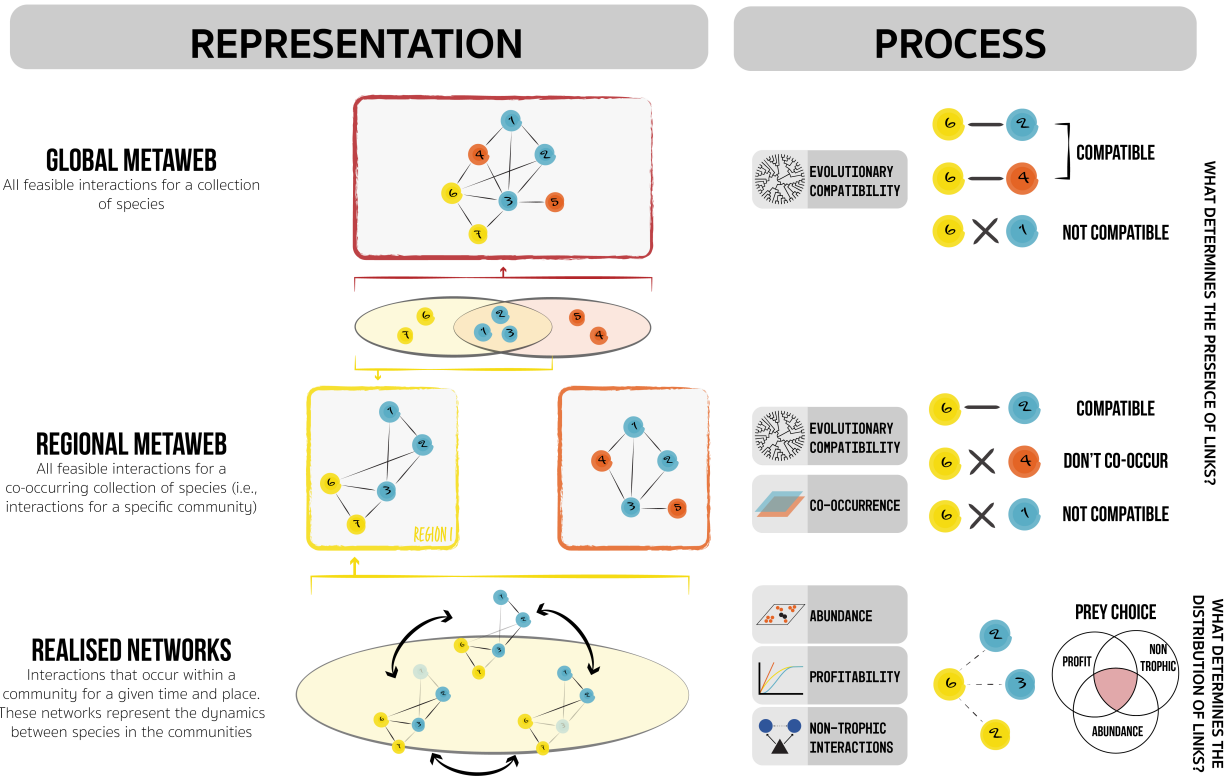

Figure 1: Aligning the various processes that determine interactions (right column) with the different network representations (left column). First, we start with a **global metaweb** this network captures all possible interactions for a collection of species in the global context. However, within the global environment different species occur in different regions (region one = yellow and region 2 = orange), and it is possible to construct two different metawebs (**regional metawebs**) for each region by taking accounting for the co-occurrence of the difference species - as shown here we have two regions with some species that are found in both regions (blue) and others endemic to either region one (yellow) or region two (orange). However even within a region we do not expect all interactions to be realised but rather that there are multiple configurations of the regional metaweb over both space and time. The ‘state’ of the different **realised networks** is ultimately influenced not just by the co-occurrence of a species pair but rather the larger community context such as the abundance of different species, maximisation of energy gain, or indirect/higher order interactions.
